Carbonyl Compounds

	Aldehydes	Ketone	
Structure	O C Ar/R/H H	O C R'/Ar'	
Condensed formula	RCOH	RCOR	
IUPAC e.g.	Methan e al	Methan e one	

Properties

- **1. pd-pd i between (polar) molecules of carbonyl compound** infer the mb/bp of cc vs alkanes/ alcohols and carboxylic acid
- 2. forms hb with water molecules but not itself
- **3. longer** the non-polar hydrocarbon chain, **greater the hinderance** to hydrogen bond formation with water molecules
- 4. solvent to dissolve polar (hb/ pd-pd i) and non-polar (id-id i) solutes

Preparation (recap)

1. Aldehydes: Mild oxidation of 1^o alcohols to aldehydes (Hydroxyl Cmpds)

acidified

$$K_2Cr_2O_7(aq)$$

RCH₂OH + [O] $\xrightarrow{K_2Cr_2O_7(aq)}$

RCHO + H₂O

immediate distillation

To obtain aldehyde as major product:

- Distil out the aldehyde once it is formed
- Use small amount of mild oxidising agent
- Use large excess of alcohol
 - N.B. Alkaline medium does not affect aldehyde
 - 2. Ketones
 - a. Oxidation of 2° alcohols to ketones (Hydroxyl Cmpds)

acidified
$$K_2Cr_2O_7(aq)$$
or

 $CH_3CH(OH)CH_3 + [O] \xrightarrow{\text{heat under reflux}} CH_3COCH_3 + H_2O$

b. Vigorous oxidation of tetra-substituted alkenes (Alkenes)

$$H_3C$$
 CH_3
 CH_3

c. FC acylation (Arenes)

Reactions

1. Nucleophilic addition

① R/C: HCN and small amount of NaOH(aq) / KOH(aq)② R/C: HCN and small amount of NaCN(aq) / KCN(aq)

Initial generation of : CN^- : ① $HCN + OH^- \rightarrow CN^- + H_2O$

 $\bigcirc NaCN \rightarrow Na^+ + CN^-$

Mechanism:

verall: small amount of ... $CH_3CHO + HCN \xrightarrow{\text{small amount of } ...} CH_3CH(OH)CN$

N.B. HCN is produced in situ due to its low bp and highly toxic nature \rightarrow small amount of H_2SO_4 added to \underline{KCN} (aq) or NaCN (aq) at $10-20^{\circ}C$

N2020/II/1ii

Suggest two reasons why potassium cyanide in slightly acidic conditions is the preferred method for forming hydroxynitriles from carbonyl compounds (2m).

CN is a weak acid that dissociate partially in water to give a small amount of CN– as the nucleophile, while KCN is a soluble salt which will give **higher amount of CN– as the nucleophiles**.

OR

HCN is **gaseous, toxic and will be more difficult to handle** as compared to solid KCN. OR

The negatively charged CN— is a **stronger nucleophile** than HCN, and the acidic condition **provides the H+ to protonate the alkoxide** in step 2.

OR

The slightly acidic conditions will **prevent excessive formation of HCN** which will lower the initial concentration of CN-(ag) and slow down the reaction)

Reactivity:

- Aldehydes are generally more reactive than ketones towards NA.

Presence of <u>more electron donating alkyl groups</u> makes <u>carbonyl carbon less e deficient</u>, <u>reducing the likelihood of</u> attack by nphile

<u>Bulky groups</u> directly bonded to carbonyl carbon <u>hinder the</u> nphile from approaching the e deficient carbonyl carbon

- **Aromatic cc is generally less reactive than aliphatic cc** due to resonance effect contributed by the aromatic ring.
- Racemic mixture can be obtained if starting carbonyl compound can be converted into chiral cyanohydrin by NA of HCN. NA can take place above and below the plane as carbonyl carbon is sp^2 hybridised

Purpose of R/C:

1 Increase ror

HCN weak acid \rightarrow POE left \rightarrow low [CN-] in rxn mixture due to partial ionisation \rightarrow rxn extremely slow \rightarrow small amount of base react away H+ \rightarrow POE right \rightarrow increase initial [CN-] to act as nphile

$$Rate = k[CN][CH_3CHO]$$

 $HCN \rightleftharpoons H^+ + CN^-$

② Provide *CN*[−] required for step 1

NaCN/ KCN is the catalyst as only HCN is used up.

2. Condensation

$$R$$
 $C = O + H_2N - Y$
 R
 $C = N - Y$
 H
 $C = N - Y$

R/C: 2,4-dinitrophenylhydrazine (2,4-DNPH) Observation: Yellow/ orange ppt formed

2,4-dinitrophenylhydrazine

Distinguishing test for carbonyl cmpds.

3. Oxidation

Help to distinguish between aldehyde and aliphatic ketones, aliphatic aldehydes

a. Using $KMnO_4$ (aq) or $K_2Cr_2O_7$ (aq)

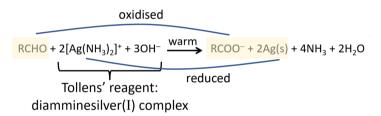

$$\begin{array}{c|c}
 & \text{acidified } K_2Cr_2O_7(aq) \\
O & or & O \\
\parallel & & \text{acidified } KMnO_4(aq) \\
\hline
R & H & + [O] & & & & \\
\hline
 & & & & & \\
 & & & & & \\
\hline
 & & & & & \\
 & & & & & \\
 & & & & & \\
\hline
 & & & & & \\
 & & & & & \\
 & & & & & \\
\hline
 & & & & & \\
 & & & & & \\
 & & & & & \\
\hline
 & & & & & \\
 & & & & & \\
\hline
 & & & & & \\
 & & & & & \\
\hline
 & & & & & \\
 & & & & & \\
\hline
 & & & & & \\
 & & & & & \\
\hline
 & & & & & \\
 & & & & & \\
\hline
 & & & & & \\
 & & & & & \\
\hline
 & & & & \\
\hline
 & & & & \\
\hline
 & & & &$$

R/C: acidified $KMnO_4$ (aq) or $K_2Cr_2o_7(aq)$, HUR Observation: Purple to colourless or orange to green

Works on aliphatic and aromatic aldehydes and aromatic ketones.

Examples on arvl ketones:

b. Tollens' Reagent

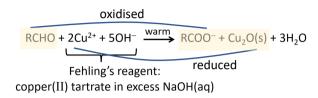

R/C: Tollens' reagent, warm

Observation: Silver mirror (formed on the wall of clean test tube) or grey/ black ppt of Ag

Works on aliphatic and aromatic aldehydes. N.B. Gives false positive with methanoic acid.

c. Fehling's Reagent

R/C: Fehling's reagent, warm

Observation: Brick red ppt of Cu_2O formed

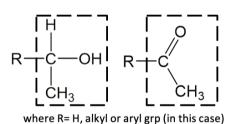

Works on aliphatic aldehydes.

4. Iodoform

R/C: I_2 in NaOH (aq), warm

Observation: (Pale) yellow pppt of tri-iodomethane CHI_3

(with characteristic antiseptic smell) formed

and other compounds formed subsequently the various steps: oxidation, substitution and hydrolysis will give positive iodoform test

5. Reduction

	$LiAlH_4$	NaBH ₄	H ₂ , Ni catalyst, heat
Charact eristics	Stronger RA	Milder RA, selective recdn	Can reduce alkene
Effects	Does not reduce alkenes as electron rich C=C bond in alkenes repel the AlH_4^- nucleophile. Reduces: - acids, esters, acid chlorides, and acid anhydrides to primary alcohols - amides to amines - nitriles to primary amines - aldehydes to primary alcohol - ketones to secondary alcohol	Reduces ald ketones
